$k_\perp$-FACTORIZATION PREDICTIONS FOR F_2^c AT HERA[a]

High energy factorization predictions for F_2^c are derived using BFKL resummations of leading logs for the proton structure functions at HERA. A theoretical non-perturbative uncertainty on the factorization scheme is taken into account by considering two different approaches for modelling the proton. The parameters are fixed by a fit of F_2 at small x. The resulting predictions for F_2^c are in agreement with the data within the present error bars.

1 High energy factorization

$k_\perp$- (or high energy) factorization [1,2] is a QCD factorization scheme suited for high-energy hard processes - and in particular for deep-inelastic $e^{\mp}$–p scattering in the small x-regime. This scheme takes into account the resummation of the $\left(\alpha_s \log \frac{1}{x}\right)^n$ terms in the QCD perturbative expansion of the structure functions.

Let us formulate $k_\perp$-factorization for the leptoproduction of a quark- antiquark pair of mass M off a small size ("perturbative") target characterized by its gluon distribution. In this scheme [1], the inclusive transverse (resp. longitudinal) structure functions F_T (F_L) can be expressed as follows:

$$F_{T,L}(Y, Q^2, M^2; Q_f^2) = \frac{1}{4\pi^2 \alpha_{em}} \frac{Q^2}{4M^2} \int_{Q_f} d^2k_\perp \int_0^\infty dy \\ \hat{\sigma}_{\gamma^* g, T, L}(Y - y, q_\perp/M, k_\perp/M)\, \mathcal{F}(y, k_\perp)\ , \quad (1)$$

where $Q^2 = -q^2$ is the virtuality of the photon, Q_f the factorization scale and M the mass of the produced quarks. Y represents the rapidity range available for the reaction. $\mathcal{F}(y, k_\perp)$ is the unintegrated gluon distribution [1], which describes the probability of finding a gluon with longitudinal momentum fraction $z = e^{-y}$ and two-dimensional transverse momentum $k_\perp$ in the target. $q_\perp$ is the photon transverse momentum. $\hat{\sigma}_{\gamma^* g, T, L}$ is the hard cross section for (virtual)photon-(virtual)gluon fusion computed at order $\alpha_s \alpha_{em}$.

The final expression for the high-energy factorized structure function is most easily expressed as an inverse Mellin transform and reads:

$$F_{T,L}(Y, Q^2, M^2; Q_f^2) = e^2 \int \frac{d\gamma}{2i\pi} \left(\frac{Q^2}{Q_f^2}\right)^\gamma h_{T,L}(\gamma; M^2)\ \frac{\mathcal{F}(Y, \gamma; Q_f^2)}{\gamma} \quad (2)$$

[a] Talk presented at the DIS98 workshop, Brussels, April 1998.

where the coefficient functions $h_{T,L}(\gamma; M^2)$ represent the Mellin-transform of the off-shell (virtual)photon-(virtual)gluon cross section, in an approximation in which one neglects subleading terms in energy. One can find their expression in [3] and [4].

$\mathcal{F}(Y, \gamma; Q_f^2)$ is the Mellin-transform of the unintegrated gluon distribution $\mathcal{F}(Y, k_\perp)$ with respect to the transverse momentum of the gluon. It is assumed to satisfy the BFKL dynamics [5]. Assuming a full factorization of the rapidity dependence, which is consistent with an asymptotic approximation for the coefficient functions, we obtain the following parametrization:

$$\frac{\mathcal{F}(Y, \gamma; Q_f^2)}{\gamma} = \omega(\gamma; Q_f^2)\ e^{\frac{\alpha_s N_c}{\pi}\chi(\gamma) Y}\ , \tag{3}$$

where $\chi(\gamma) = 2\Psi(1) - \Psi(\gamma) - \Psi(1{-}\gamma)$. The function $\omega(\gamma; Q_f^2)$ will explicitly depend on the nature of the target, and has to be supplied by a model for an extended target like a proton, see next section.

2 Phenomenology

Let us introduce the model for the proton. Following the suggestion of ref. [6], one assumes the scaling form $\omega(\gamma; Q_f^2) = \omega(\gamma)(Q_f/Q_0)^{2\gamma}$, where Q_0 is a non-perturbative scale, independent of the mass M. With this assumption, the overall formula (2) does no more depend on the factorization scale Q_f.

We have shown in ref. [4] that the behaviour of $\omega(\gamma)$ when γ becomes large cannot be steeper than a polynomial. This constraint comes from the region where $k_\perp$ is large, i.e. where we expect rather a DGLAP evolution. Taking into account this constraint, we will now focus on two definite models relying on different formulations of the residue function $\omega(\gamma)$ at small γ. On the one hand, the model 1, with $\omega(\gamma) = C$(constant) corresponds to the factorization at the gluon level: all the perturbative content of $k_\perp$-factorization is kept. On the other hand, in model 2, we consider an input compensating the $1/\gamma$ pole of $h_T(\gamma; M^2)$: $\omega(\gamma) \sim \gamma C$ at small γ. This model corresponds to a factorization at the quark level [7], and was discussed in ref. [4]. Both models lead to an expression for the proton structure functions depending on three free parameters, C, α_s, and Q_0.

We determine these parameters for both models by a fit of $F_2 = F_T + F_L$ in their kinematical region of validity ($x \leq 10^{-2}$, moderate Q^2). Using the corresponding 103 experimental points given by the H1 collaboration [8], we fit our results (2) with the contribution of the three light quarks u, d, s (assumed massless) and of the charm quark (mass M_c). The F_2-fit for the medium mass $M_c = 1.5$ GeV is displayed in figure 1, together with the predictions for its

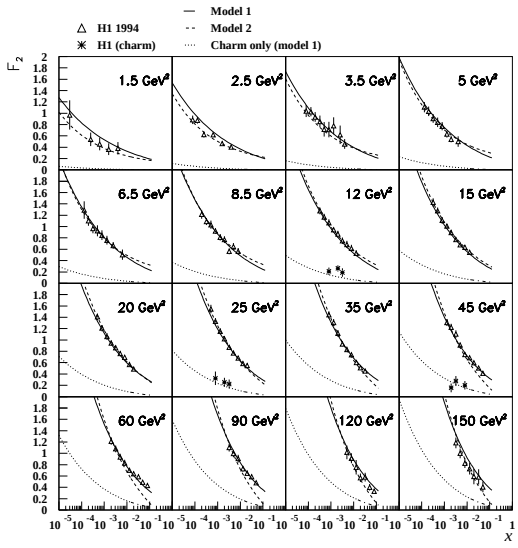

Figure 1: The fits (model 1 and model 2) for the structure function F_2. The structure function F_2 and its parametrization are displayed for model 1 and model 2. dotted line: prediction for the charm component F_2^c, for $M_c = 1.5$ GeV and model 1. The available H1 data are marked by stars.

charm component F_2^c. For model 1, the χ^2 per point is always less than 0.9, while for model 2 it is even lower. For model 1, the value of Q_0 is around 330 MeV which is a typical non perturbative scale for the proton. The value of the effective coupling constant in the BFKL mechanism α_s (0.07) is rather low. For model 2, the data for F_2 are also fairly well reproduced (see figure 1). Note that the value of $Q_0 \simeq 1.2$ GeV is substantially higher and the effective coupling constant α_s is a bit larger ($\simeq \alpha_s(M_Z)$).

The parameter free predictions [4] for F_2^c obtained as an outcome of both of the considered models are in good agreement with ZEUS and H1 data [9], within the present experimental error bars, although model 2 predicts a significantly higher charm component. The predictions are also comparable to the next-leading order prediction [10] based on the GRV parton distribution set [11] which proves that F_2^c cannot allow one to distinguish between the two approaches.

3 Conclusions

The high energy factorization scheme provides us with some good predictions for F_2^c which are weakly dependent on the non perturbative input, within the

present error bars on the data. However, one model predicts rather higher F_2^c. More precise data could help to distinguish between both models. A good parametrization for the total structure function F_2 was obtained (3 parameters only are required), but the low value obtained for the effective coupling constant α_s may be an indication of the strong next-leading order BFKL recently computed[12], which might have been taken into account effectively in these fits. Anyway, it seems not to spoil the $k_\perp$-factorization predictions.

Acknowledgments

The material of this contribution is the result of a collaboration with R. Peschanski. We also thank S. Catani for fruitful suggestions, H. Navelet and Ch. Royon for stimulating discussions and comments.
